# Chapter 12: Query Processing

## Chapter 12: Query Processing

- Overview
- Measures of Query Cost
- Selection Operation
- Sorting
- Join Operation
- Other Operations
- Evaluation of Expressions

### Basic Steps in Query Processing

- 1. Parsing and translation
- 2. Optimization
- 3. Evaluation

# Basic Steps in Query Processing (Cont.)

- Parsing and translation
  - translate the query into its internal form. This is then translated into relational algebra.
  - Parser checks syntax, verifies relations
- Evaluation
  - The query-execution engine takes a query-evaluation plan, executes that plan, and returns the answers to the query.

# Basic Steps in Query Processing: Optimization

- A relational algebra expression may have many equivalent expressions
  - E.g.,  $\sigma_{salary < 75000}(\prod_{salary}(instructor))$  is equivalent to  $\prod_{salary}(\sigma_{salary < 75000}(instructor))$
- Each relational algebra operation can be evaluated using one of several different algorithms
  - Correspondingly, a relational-algebra expression can be evaluated in many ways.
- Annotated expression specifying detailed evaluation strategy is called an evaluation-plan.
  - E.g., can use an index on *salary* to find instructors with salary < 75000,
  - or can perform complete relation scan and discard instructors with salary  $\geq$  75000

#### Basic Steps: Optimization (Cont.)

- Query Optimization: Amongst all equivalent evaluation plans choose the one with lowest cost.
  - Cost is estimated using statistical information from the database catalog
    - e.g. number of tuples in each relation, size of tuples, etc.
- In this chapter we study
  - How to measure query costs
  - Algorithms for evaluating relational algebra operations
  - How to combine algorithms for individual operations in order to evaluate a complete expression
- In Chapter 14
  - We study how to optimize queries, that is, how to find an evaluation plan with lowest estimated cost

#### Measures of Query Cost

- Cost is generally measured as total elapsed time for answering query
  - Many factors contribute to time cost
    - disk accesses, CPU, or even network communication
- Typically disk access is the predominant cost, and is also relatively easy to estimate. Measured by taking into account
  - Number of seeks\* average-seek-cost
  - Number of blocks read \* average-block-read-cost
  - Number of blocks written \* average-block-write-cost
    - Cost to write a block is greater than cost to read a block
      - data is read back after being written to ensure that the write was successful

### Measures of Query Cost (Cont.)

- For simplicity we just use the number of block transfers from disk and the number of seeks as the cost measures
  - $t_T$  time to transfer one block
  - $t_s$  time for one seek
  - Cost for b block transfers plus S seeks

$$b * t_T + S * t_S$$

- We ignore CPU costs for simplicity
  - Real systems do take CPU cost into account
- We do not include cost to writing output to disk in our cost formulae

#### Measures of Query Cost (Cont.)

- Several algorithms can reduce disk IO by using extra buffer space
  - Amount of real memory available to buffer depends on other concurrent queries and OS processes, known only during execution
    - We often use worst case estimates, assuming only the minimum amount of memory needed for the operation is available
- Required data may be buffer resident already, avoiding disk I/O
  - But hard to take into account for cost estimation

#### Selection Operation

- File scan
- Algorithm A1 (linear search). Scan each file block and test all records to see whether they satisfy the selection condition.
  - Cost estimate =  $b_r$  block transfers + 1 seek
    - $b_r$  denotes number of blocks containing records from relation r
  - If selection is on a key attribute, can stop on finding record
    - $cost = (b_r/2)$  block transfers + 1 seek
  - Linear search can be applied regardless of
    - selection condition or
    - ordering of records in the file, or
    - availability of indices
- Note: binary search generally does not make sense since data is not stored consecutively
  - except when there is an index available,
  - and binary search requires more seeks than index search

#### Selection Operation (Cont.)

- **Old-A2** (binary search). Applicable if selection is an equality comparison on the attribute on which file is ordered.
  - Assume that the blocks of a relation are stored contiguously
  - Cost estimate (number of disk blocks to be scanned):
    - cost of locating the first tuple by a binary search on the blocks
      - $\bullet \lceil \log_2(b_r) \rceil * (t_T + t_S)$
    - If there are multiple records satisfying selection
      - Add transfer cost of the number of blocks containing records that satisfy selection condition
      - Will see how to estimate this cost in Chapter 13

### Selections Using Indices

- Index scan search algorithms that use an index
  - selection condition must be on search-key of index.
- A2 (primary index, equality on key). Retrieve a single record that satisfies the corresponding equality condition
  - $Cost = (h_i + 1) * (t_T + t_S)$
- A3 (primary index, equality on nonkey) Retrieve multiple records.
  - Records will be on consecutive blocks
    - Let b = number of blocks containing matching records
  - $Cost = h_i * (t_T + t_S) + t_S + t_T * b$

#### Selections Using Indices

- A4 (secondary index, equality on nonkey).
  - Retrieve a single record if the search-key is a candidate key
    - $Cost = (h_i + 1) * (t_T + t_S)$
  - Retrieve multiple records if search-key is not a candidate key
    - each of n matching records may be on a different block
    - $\bullet \quad \text{Cost} = (h_i + n) * (t_T + t_S)$ 
      - Can be very expensive!

#### Selections Involving Comparisons

- Can implement selections of the form  $\sigma_{A \leq V}(r)$  or  $\sigma_{A \geq V}(r)$  by using
  - a linear file scan,
  - or by using indices in the following ways:
- **A5** (**primary index, comparison**). (Relation is sorted on A)
  - For  $\sigma_{A \geq V}(r)$  use index to find first tuple  $\geq v$  and scan relation sequentially from there
  - For  $\sigma_{A \leq V}(r)$  just scan relation sequentially till first tuple > v; do not use index
- A6 (secondary index, comparison).
  - For  $\sigma_{A \geq V}(r)$  use index to find first index entry  $\geq v$  and scan index sequentially from there, to find pointers to records.
  - For  $\sigma_{A \leq V}(r)$  just scan leaf pages of index finding pointers to records, till first entry  $>_V$
  - In either case, retrieve records that are pointed to
    - requires an I/O for each record
    - Linear file scan may be cheaper

#### Implementation of Complex Selections

- Conjunction:  $\sigma_{\theta_1} \wedge \sigma_{\theta_2} \wedge \dots \sigma_{\theta_n}(r)$
- A7 (conjunctive selection using one index).
  - Select a combination of  $\theta_i$  and algorithms A1 through A7 that results in the least cost for  $\sigma_{\theta_i}(r)$ .
  - Test other conditions on tuple after fetching it into memory buffer.
- A8 (conjunctive selection using composite index).
  - Use appropriate composite (multiple-key) index if available.
- A9 (conjunctive selection by intersection of identifiers).
  - Requires indices with record pointers.
  - Use corresponding index for each condition, and take intersection of all the obtained sets of record pointers.
  - Then fetch records from file
  - If some conditions do not have appropriate indices, apply test in memory.

### Algorithms for Complex Selections

- **Disjunction:**  $\sigma_{\theta_1} \vee \sigma_{\theta_2} \vee \dots \sigma_{\theta_n}(r)$ .
- A10 (disjunctive selection by union of identifiers).
  - Applicable if *all* conditions have available indices.
    - Otherwise use linear scan.
  - Use corresponding index for each condition, and take union of all the obtained sets of record pointers.
  - Then fetch records from file
- Negation:  $\sigma_{-\theta}(r)$ 
  - Use linear scan on file
  - If very few records satisfy  $-\theta$ , and an index is applicable to  $\theta$ 
    - Find satisfying records using index and fetch from file

### Sorting

- We may build an index on the relation, and then use the index to read the relation in sorted order. May lead to one disk block access for each tuple.
- For relations that fit in memory, techniques like quicksort can be used. For relations that don't fit in memory, external
   sort-merge is a good choice.

#### External Sort-Merge

#### Let M denote memory size (in pages).

1. **Create sorted runs**. Let *i* be 0 initially.

Repeatedly do the following till the end of the relation:

- (a) Read *M* blocks of relation into memory
- (b) Sort the in-memory blocks
- (c) Write sorted data to run  $R_i$ ; increment i.

Let the final value of i be N

2. Merge the runs (next slide).....

#### External Sort-Merge (Cont.)

- 2. Merge the runs (N-way merge). We assume (for now) that N < M.
  - 1. Use *N* blocks of memory to buffer input runs, and 1 block to buffer output. Read the first block of each run into its buffer page

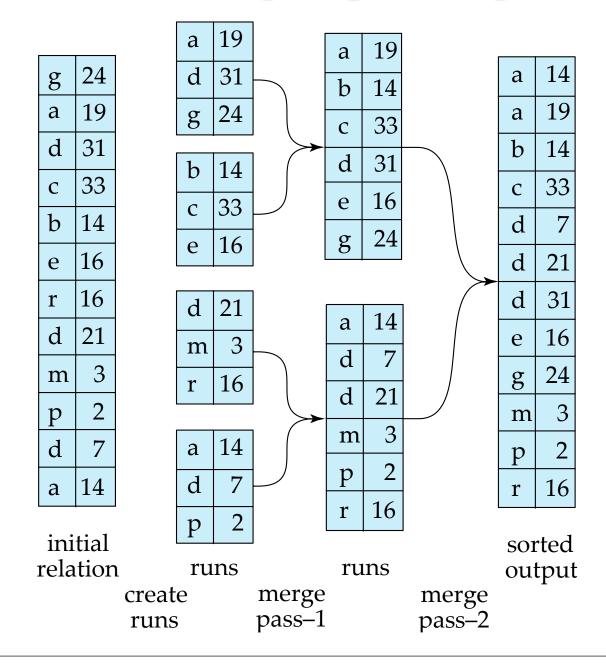

#### 2. repeat

- 1. Select the first record (in sort order) among all buffer pages
- 2. Write the record to the output buffer. If the output buffer is full write it to disk.
- 3. Delete the record from its input buffer page.
  If the buffer page becomes empty then
  read the next block (if any) of the run into the buffer.
- **3. until** all input buffer pages are empty:

#### External Sort-Merge (Cont.)

- If  $N \ge M$ , several merge passes are required.
  - In each pass, contiguous groups of M 1 runs are merged.
  - A pass reduces the number of runs by a factor of M -1, and creates runs longer by the same factor.
    - E.g. If M=11, and there are 90 runs, one pass reduces the number of runs to 9, each 10 times the size of the initial runs
  - Repeated passes are performed till all runs have been merged into one.

#### Example: External Sorting Using Sort-Merge

### External Merge Sort (Cont.)

- Cost analysis:
  - 1 block per run leads to too many seeks during merge
    - Instead use  $b_b$  buffer blocks per run
      - $\rightarrow$  read/write  $b_b$  blocks at a time
    - Can merge  $\lfloor M/b_b \rfloor 1$  runs in one pass
  - Total number of merge passes required:  $|\log_{\lfloor M/bb \rfloor}(b_r/M)|$ .
  - Block transfers for initial run creation as well as in each pass is  $2b_r$ 
    - for final pass, we don't count write cost
      - we ignore final write cost for all operations since the output of an operation may be sent to the parent operation without being written to disk
    - Thus total number of block transfers for external sorting:  $b_r(2\lceil \log_{\lfloor M/bb \rfloor-1}(b_r/M) \rceil + 1) \lceil$
  - Seeks: next slide

## External Merge Sort (Cont.)

- Cost of seeks
  - During run generation: one seek to read each run and one seek to write each run
    - $2 \lceil b_r / M \rceil$
  - During the merge phase
    - Need  $2 \lceil b_r / b_b \rceil$  seeks for each merge pass
      - except the final one which does not require a write
    - Total number of seeks:

$$2\lceil b_r / M \rceil + \lceil b_r / b_b \rceil (2\lceil \log_{M/bb} \lfloor (b_r / M) \rceil - 1)$$

#### Join Operation

- Several different algorithms to implement joins
  - Nested-loop join
  - Block nested-loop join
  - Indexed nested-loop join
  - Merge-join
  - Hash-join
- Choice based on cost estimate
- Examples use the following information
  - Number of records of student: 5,000 takes: 10,000
  - Number of blocks of student: 100 takes: 400

#### Nested-Loop Join

```
• To compute the theta join r 	hinspace 0 f or each tuple t_r in r do begin for each tuple t_s in s do begin test pair (t_r, t_s) to see if they satisfy the join condition \theta if they do, add t_r 	hinspace t_s to the result. end end
```

- r is called the **outer relation** and s the **inner relation** of the join.
- Requires no indices and can be used with any kind of join condition.
- Expensive since it examines every pair of tuples in the two relations.

#### Nested-Loop Join (Cont.)

• In the worst case, if there is enough memory only to hold one block of each relation, the estimated cost is

$$n_r * b_s + b_r$$
 block transfers, plus  $n_r + b_r$  seeks

- If the smaller relation fits entirely in memory, use that as the inner relation.
  - Reduces cost to  $b_r + b_s$  block transfers and 2 seeks
- Assuming worst case memory availability cost estimate is
  - with *student* as outer relation:
    - 5000 \* 400 + 100 = 2,000,100 block transfers,
    - 5000 + 100 = 5100 seeks
  - with *takes* as the outer relation
    - 10000 \* 100 + 400 = 1,000,400 block transfers and 10,400 seeks
- If smaller relation (*student*) fits entirely in memory, the cost estimate will be 500 block transfers.
- Block nested-loops algorithm (next slide) is preferable.

#### Block Nested-Loop Join

• Variant of nested-loop join in which every block of inner relation is paired with every block of outer relation.

```
for each block B_r of r do begin

for each block B_s of s do begin

for each tuple t_r in B_r do begin

for each tuple t_s in B_s do begin

Check if (t_r, t_s) satisfy the join condition

if they do, add t_r \cdot t_s to the result.

end

end

end

end
```

#### Block Nested-Loop Join (Cont.)

- Worst case estimate:  $b_r * b_s + b_r$  block transfers  $+ 2 * b_r$  seeks
  - Each block in the inner relation *s* is read once for each *block* in the outer relation
- Best case:  $b_r + b_s$  block transfers + 2 seeks.
- Improvements to nested loop and block nested loop algorithms:
  - In block nested-loop, use M 2 disk blocks as blocking unit for outer relations, where M = memory size in blocks; use remaining two blocks to buffer inner relation and output
    - Cost =  $\lceil b_r / (M-2) \rceil * b_s + b_r$  block transfers +  $2 \lceil b_r / (M-2) \rceil$  seeks
  - If equi-join attribute forms a key or inner relation, stop inner loop on first match
  - Scan inner loop forward and backward alternately, to make use of the blocks remaining in buffer (with LRU replacement)
  - Use index on inner relation if available (next slide)

#### Indexed Nested-Loop Join

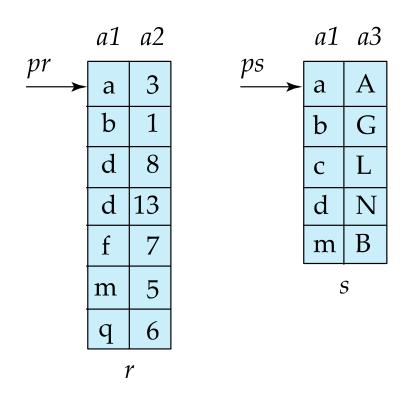

- Index lookups can replace file scans if
  - join is an equi-join or natural join and
  - an index is available on the inner relation's join attribute
    - Can construct an index just to compute a join.
- For each tuple  $t_r$  in the outer relation r, use the index to look up tuples in s that satisfy the join condition with tuple  $t_r$ .
- Worst case: buffer has space for only one page of r, and, for each tuple in r, we perform an index lookup on s.
- Cost of the join:  $b_r(t_T + t_S) + n_r * c$ 
  - Where *c* is the cost of traversing index and fetching all matching *s* tuples for one tuple or *r*
  - c can be estimated as cost of a single selection on s using the join condition.
- If indices are available on join attributes of both r and s, use the relation with fewer tuples as the outer relation.

### Example of Nested-Loop Join Costs

- Compute *student*  $\bowtie$  *takes*, with *student* as the outer relation.
- Let *takes* have a primary B<sup>+</sup>-tree index on the attribute *ID*, which contains 20 entries in each index node.
- Since *takes* has 10,000 tuples, the height of the tree is 4, and one more access is needed to find the actual data
- *student* has 5000 tuples
- Cost of block nested loops join
  - 400\*100 + 100 = 40,100 block transfers + 2 \* 100 = 200 seeks
    - assuming worst case memory
    - may be significantly less with more memory
- Cost of indexed nested loops join
  - 100 + 5000 \* 5 = 25,100 block transfers and seeks.
  - CPU cost likely to be less than that for block nested loops join

#### Merge-Join

- 1. Sort both relations on their join attribute (if not already sorted on the join attributes).
- 2. Merge the sorted relations to join them
  - 1. Join step is similar to the merge stage of the sort-merge algorithm.
  - 2. Main difference is handling of duplicate values in join attribute every pair with same value on join attribute must be matched
  - 3. Detailed algorithm in book

### Merge-Join (Cont.)

- Can be used only for equi-joins and natural joins
- Each block needs to be read only once (assuming all tuples for any given value of the join attributes fit in memory
- Thus the cost of merge join is:  $b_r + b_s$  block transfers  $+ \lceil b_r / b_b \rceil + \lceil b_s / b_b \rceil$  seeks
  - + the cost of sorting if relations are unsorted.
- **hybrid merge-join:** If one relation is sorted, and the other has a secondary B<sup>+</sup>-tree index on the join attribute
  - ullet Merge the sorted relation with the leaf entries of the  $B^+$ -tree .
  - Sort the result on the addresses of the unsorted relation's tuples
  - Scan the unsorted relation in physical address order and merge with previous result, to replace addresses by the actual tuples
    - Sequential scan more efficient than random lookup

#### Hash-Join

- Applicable for equi-joins and natural joins.
- A hash function *h* is used to partition tuples of both relations
- h maps JoinAttrs values to  $\{0, 1, ..., n\}$ , where JoinAttrs denotes the common attributes of r and s used in the natural join.
  - $r_0, r_1, \ldots, r_n$  denote partitions of r tuples
    - Each tuple  $t_r \in r$  is put in partition  $r_i$  where  $i = h(t_r[JoinAttrs])$ .
  - $r_0, r_1, \ldots, r_n$  denotes partitions of s tuples
    - Each tuple  $t_s \in s$  is put in partition  $s_i$ , where  $i = h(t_s[JoinAttrs])$ .
- Note: In book,  $r_i$  is denoted as  $H_{ri,s_i}$  is denoted as  $H_{si}$  and n is denoted as  $n_h$

# Hash-Join (Cont.) partitions of *r* partitions of *s*

#### Hash-Join (Cont.)

- r tuples in  $r_i$  need only to be compared with s tuples in  $s_i$  Need not be compared with s tuples in any other partition, since:
  - an *r* tuple and an *s* tuple that satisfy the join condition will have the same value for the join attributes.
  - If that value is hashed to some value i, the r tuple has to be in  $r_i$  and the s tuple in  $s_i$ .

#### Hash-Join Algorithm

#### The hash-join of *r* and *s* is computed as follows.

- 1. Partition the relation *s* using hashing function *h*. When partitioning a relation, one block of memory is reserved as the output buffer for each partition.
- 2. Partition *r* similarly.
- 3. For each *i*:
  - (a) Load  $s_i$  into memory and build an in-memory hash index on it using the join attribute. This hash index uses a different hash function than the earlier one h.
  - (b) Read the tuples in  $r_i$  from the disk one by one. For each tuple  $t_r$  locate each matching tuple  $t_s$  in  $s_i$  using the in-memory hash index. Output the concatenation of their attributes.

Relation s is called the **build input** and r is called the **probe input**.

#### Hash-Join algorithm (Cont.)

- The value *n* and the hash function *h* is chosen such that each *s*<sub>*i*</sub> should fit in memory.
  - Typically n is chosen as  $\lceil b_S/M \rceil * f$  where f is a "fudge factor", typically around 1.2
  - The probe relation partitions  $s_i$  need not fit in memory
- Recursive partitioning required if number of partitions n is greater than number of pages M of memory.
  - instead of partitioning n ways, use M-1 partitions for s
  - Further partition the M-1 partitions using a different hash function
  - Use same partitioning method on r
  - Rarely required: e.g., with block size of 4 KB, recursive partitioning not needed for relations of < 1GB with memory size of 2MB, or relations of < 36 GB with memory of 12 MB</li>

#### Handling of Overflows

- Partitioning is said to be **skewed** if some partitions have significantly more tuples than some others
- Hash-table overflow occurs in partition  $s_i$  if  $s_i$  does not fit in memory. Reasons could be
  - Many tuples in s with same value for join attributes
  - Bad hash function
- Overflow resolution can be done in build phase
  - Partition  $s_i$  is further partitioned using different hash function.
  - Partition  $r_i$  must be similarly partitioned.
- Overflow avoidance performs partitioning carefully to avoid overflows during build phase
  - E.g. partition build relation into many partitions, then combine them
- Both approaches fail with large numbers of duplicates
  - Fallback option: use block nested loops join on overflowed partitions

#### Cost of Hash-Join

• If recursive partitioning is not required: cost of hash join is

$$3(b_r + b_s) + 4 * n_h$$
 block transfers +  $2(\lceil b_r / b_h \rceil + \lceil b_s / b_h \rceil)$  seeks

- If recursive partitioning required:
  - number of passes required for partitioning build relation s to less than M blocks per partition is  $\lceil \log_{M/bb} \lfloor 1(b_s/M) \rceil$
  - best to choose the smaller relation as the build relation.
  - Total cost estimate is:

$$2(b_r + b_s) \lceil \log_{M/bb} \rfloor_{-1} (b_s/M) \rceil + b_r + b_s \text{ block transfers} + 2(\lceil b_r/b_b \rceil + \lceil b_s/b_b \rceil) \lceil \log_{M/bb} \rfloor_{-1} (b_s/M) \rceil \text{ seeks}$$

- If the entire build input can be kept in main memory no partitioning is required
  - Cost estimate goes down to  $b_r + b_s$ .

#### Example of Cost of Hash-Join

#### *instructor* ⋈ *teaches*

- Assume that memory size is 20 blocks
- $b_{instructor} = 100$  and  $b_{teaches} = 400$ .
- *instructor* is to be used as build input. Partition it into five partitions, each of size 20 blocks. This partitioning can be done in one pass.
- Similarly, partition *teaches* into five partitions, each of size 80. This is also done in one pass.
- Therefore total cost, ignoring cost of writing partially filled blocks:
  - 3(100 + 400) = 1500 block transfers +  $2(\lceil 100/3 \rceil + \lceil 400/3 \rceil) = 336$  seeks

#### Hybrid Hash-Join

- Useful when memory sized are relatively large, and the build input is bigger than memory.
- Main feature of hybrid hash join:Keep the first partition of the build relation in memory.
- E.g. With memory size of 25 blocks, *instructor* can be partitioned into five partitions, each of size 20 blocks.
  - Division of memory:
    - The first partition occupies 20 blocks of memory
    - 1 block is used for input, and 1 block each for buffering the other 4 partitions.
- teaches is similarly partitioned into five partitions each of size 80
  - the first is used right away for probing, instead of being written out
- Cost of 3(80 + 320) + 20 + 80 = 1300 block transfers for hybrid hash join, instead of 1500 with plain hash-join.
- Hybrid hash-join most useful if M >>

#### Complex Joins

• Join with a conjunctive condition:

$$\theta_1 \wedge \theta_2 \wedge \dots \wedge \theta_n$$

- Either use nested loops/block nested loops, or
- Compute the result of one of the simpler joins  $r = \theta_i s$ 
  - final result comprises those tuples in the intermediate result that satisfy the remaining conditions

$$\theta_1 \wedge \ldots \wedge \theta_{i-1} \wedge \theta_{i+1} \wedge \ldots \wedge \theta_n$$

• Join with a disjunctive condition

$$r$$
  $\theta_1 \vee \theta_2 \vee ... \vee \theta_n$ 

- Either use nested loops/block nested loops, or
- Compute as the union of the records in individual joins  $r = \theta_i s$ :

$$(r \qquad \theta_1 s) \cup (r \qquad \theta_2 s) \cup \ldots \cup (r \qquad \theta_n s)$$

$$\bowtie \qquad \bowtie$$

#### Other Operations

- Duplicate elimination can be implemented via hashing or sorting.
  - On sorting duplicates will come adjacent to each other, and all but one set of duplicates can be deleted.
  - *Optimization:* duplicates can be deleted during run generation as well as at intermediate merge steps in external sort-merge.
  - Hashing is similar duplicates will come into the same bucket.

#### • Projection:

- perform projection on each tuple
- followed by duplicate elimination.

#### Other Operations: Aggregation

- Aggregation can be implemented in a manner similar to duplicate elimination.
  - Sorting or hashing can be used to bring tuples in the same group together, and then the aggregate functions can be applied on each group.
  - Optimization: combine tuples in the same group during run generation and intermediate merges, by computing partial aggregate values
    - For count, min, max, sum: keep aggregate values on tuples found so far in the group.
      - When combining partial aggregate for count, add up the aggregates
    - For avg, keep sum and count, and divide sum by count at the end

#### Other Operations: Set Operations

- **Set operations** ( $\cup$ ,  $\cap$  and  $\longrightarrow$ ): can either use variant of merge-join after sorting, or variant of hash-join.
- E.g., Set operations using hashing:
  - 1. Partition both relations using the same hash function
  - 2. Process each partition *i* as follows.
    - 1. Using a different hashing function, build an in-memory hash index on  $r_i$ .
    - 2. Process  $s_i$  as follows
      - $r \cup s$ :
        - 1. Add tuples in  $s_i$  to the hash index if they are not already in it.
        - 2. At end of  $s_i$  add the tuples in the hash index to the result.

### Other Operations: Set Operations

- E.g., Set operations using hashing:
  - 1. as before partition r and s,
  - 2. as before, process each partition *i* as follows
    - 1. build a hash index on  $r_i$
    - 2. Process  $s_i$  as follows
      - $r \cap s$ :
        - 1. output tuples in  $s_i$  to the result if they are already there in the hash index
      - r-s:
        - 1. for each tuple in  $s_i$ , if it is there in the hash index, delete it from the index.
        - 2. At end of  $s_i$  add remaining tuples in the hash index to the result.

#### Other Operations: Outer Join

- Outer join can be computed either as
  - A join followed by addition of null-padded non-participating tuples.
  - by modifying the join algorithms.
- Modifying merge join to compute r
  - In r s, non participating tuples are those in  $r \prod_{R}(r s)$
  - Modify merge-join to compute *r* s:
    - During merging, for every tuple  $t_r$  from  $\underline{r}$  that do not match any tuple in s, output  $t_r$  padded with nulls.
  - Right outer-join and full outer-join can be computed similarly.

#### Other Operations: Outer Join

- Modifying hash join to compute r s
  - If r is probe relation, output non-matching r tuples padded with nulls
  - If r is build relation, when probing keep track of which r tuples matched s tuples. At end of  $s_i$  output non-matched r tuples padded with nulls

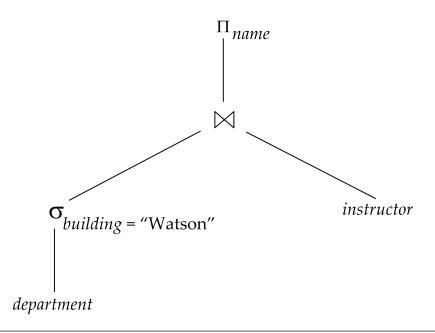

#### **Evaluation of Expressions**

- So far: we have seen algorithms for individual operations
- Alternatives for evaluating an entire expression tree
  - Materialization: generate results of an expression whose inputs are relations or are already computed, materialize (store) it on disk. Repeat.
  - Pipelining: pass on tuples to parent operations even as an operation is being executed
- We study above alternatives in more detail

#### Materialization

- Materialized evaluation: evaluate one operation at a time, starting at the lowest-level. Use intermediate results materialized into temporary relations to evaluate next-level operations.
- E.g., in figure below, compute and store

then compute the store "Watson" (department) with instructor, and finally compute the projection on name.

#### Materialization (Cont.)

- Materialized evaluation is always applicable
- Cost of writing results to disk and reading them back can be quite high
  - Our cost formulas for operations ignore cost of writing results to disk, so
    - Overall cost = Sum of costs of individual operations + cost of writing intermediate results to disk
- **Double buffering**: use two output buffers for each operation, when one is full write it to disk while the other is getting filled
  - Allows overlap of disk writes with computation and reduces execution time

### Pipelining

- **Pipelined evaluation:** evaluate several operations simultaneously, passing the results of one operation on to the next.
- E.g., in previous expression tree, don't store result of

#### $\sigma_{building="Watson"}(department)$

- instead, pass tuples directly to the join. Similarly, don't store result of join, pass tuples directly to projection.
- Much cheaper than materialization: no need to store a temporary relation to disk.
- Pipelining may not always be possible e.g., sort, hash-join.
- For pipelining to be effective, use evaluation algorithms that generate output tuples even as tuples are received for inputs to the operation.
- Pipelines can be executed in two ways: demand driven and producer driven

# Pipelining (Cont.)

- In demand driven or lazy evaluation
  - system repeatedly requests next tuple from top level operation
  - Each operation requests next tuple from children operations as required, in order to output its next tuple
  - In between calls, operation has to maintain "state" so it knows what to return next
- In producer-driven or eager pipelining
  - Operators produce tuples eagerly and pass them up to their parents
    - Buffer maintained between operators, child puts tuples in buffer, parent removes tuples from buffer
    - if buffer is full, child waits till there is space in the buffer, and then generates more tuples
  - System schedules operations that have space in output buffer and can process more input tuples
- Alternative name: pull and push models of pipelining

# Pipelining (Cont.)

- Implementation of demand-driven pipelining
  - Each operation is implemented as an **iterator** implementing the following operations
    - open()
      - E.g. file scan: initialize file scan
        - o state: pointer to beginning of file
      - E.g.merge join: sort relations;
        - state: pointers to beginning of sorted relations
    - next()
      - E.g. for file scan: Output next tuple, and advance and store file pointer
      - E.g. for merge join: continue with merge from earlier state till next output tuple is found. Save pointers as iterator state.
    - close()

# Evaluation Algorithms for Pipelining

- Some algorithms are not able to output results even as they get input tuples
  - E.g. merge join, or hash join
  - intermediate results written to disk and then read back
- Algorithm variants to generate (at least some) results on the fly, as input tuples are read in
  - E.g. hybrid hash join generates output tuples even as probe relation tuples in the in-memory partition (partition 0) are read in
  - Double-pipelined join technique: Hybrid hash join, modified to buffer partition 0 tuples of both relations in-memory, reading them as they become available, and output results of any matches between partition 0 tuples
    - When a new  $r_0$  tuple is found, match it with existing  $s_0$  tuples, output matches, and save it in  $r_0$
    - Symmetrically for s<sub>0</sub> tuples
